Abstract: The process industries exhibit an increasing need for efficient management of all the factors that can reduce their operating costs, leading to the necessity for a global multi-objective optimization methodology that will enable the generation of optimum strategies, fulfilling the required restrictions. In this paper a genetic algorithm is developed and applied for the optimal assignment of all the production sections in a particular mill in the kraft pulp and paper industry, in order to optimize energy the costs and production rate changes. This system is intended to implement all programmed or forced maintenance shutdowns, as well as all the reductions imposed in production rates.

Keywords: Production control, scheduling algorithms, genetic algorithms, global optimization, pulp industry.

1. INTRODUCTION

Plants in the continuous production industries can be described as groups of departments, each responsible for some specific operations and separated by intermediate buffers. The production of kraft pulp and paper is one of such industries.

Consider the notation of Fig. 1, suggested in (Dourado and Santos, 1993), where buffer j, with level x_j (j = 1, ..., m), receives the production from the department i, working at rate u_i (i = 1, ..., n) units, and delivers the raw material to department i + 1, working at rate u_{i+1} units; $b_{j,i+1} \cdot u_{i+1}$ units are consumed from buffer j for

each unit of production u_{i+1} . This work is based on the case study of the flowsheet of Centro Fabril de Viana da Portucel, represented in Fig. 5.

Fig. 1. Flowsheet example with two departments and one buffer.

Pulp mills (and in general the continuous production industry mills) are complex systems, where shutdowns and disturbances are propagated throughout the plant and influence the whole mill. This may lead to mass and energy losses due to transient incorrect chemical dosing, and consequently to production losses by breakdowns in

the quality levels. The task of scheduling must minimize these effects.

2. THE PRODUCTION SCHEDULING

The stock equation (1) represents the overall discrete model for the production coordination, where B is the mass balance matrix, and control vector u and state vector x are the departments' production rates and the intermediate-level buffers, respectively. T is the discretization interval, N is the number of discrete planning intervals and $k = 0, \ldots, N-1$.

$$x(k+1) = x(k) + B \cdot T \cdot u(k) \tag{1}$$

Both control u and state x are physically constrained by eqs (2) and (3).

$$0 \le u_{\min}(k) \le u(k) \le u_{\max}(k) \le U_{\max}(2)$$

$$0 \le x_{\min}(k) \le x(k) \le x_{\max}(k) \le X_{\max}(3)$$

In the presented flowsheet here there are three departments that exhibit some different behaviors from the rest, and therefore require special attention: the water (collection and treatment) department, the auxiliary boiler and the turbogenerator.

The water department produces filtered water for consumption in the various mill departments, and so the production rate is dependent on the rest of the mill. This situation leads to a representation of the water production (4), where FW is the filtered water production and D_{water} is the water balance matrix.

$$FW = D_{water} \cdot u \tag{4}$$

The task of the auxiliary boiler, together with the recovery boiler, is to produce high-pressure steam (HPS) (the recovery boiler also produces green liquor). The two boilers must fulfil the requirements of HPS in the mill. The mill also needs medium-pressure steam (MPS) and low-pressure steam (LPS) in several sections, namely the paper machine, the pulp mill, the evaporation, the causticizing, and the energy sector. Equations (6) and (5) express the relation between the input (HPS) and the output (MPS, LPS, condensed water and electrical energy) in the turbogenerator, where <math>HPS, MPS, LPS and CW (condensed water) are given in kg, and the electrical energy (EE_{trbgnr}) is given in $kW \cdot h$.

$$EE_{trbgnr} = (MPS \cdot 77.5 + LPS \cdot 117.5 + (5)$$
$$CW \cdot 178.0) \cdot \frac{0.7}{860.5}$$

$$HPS = MPS + LPS + CW \tag{6}$$

By an analysis of the production values, the turbogenerator production rates are kept at the

minimum to maintain the needed output flow of MPS and LPS. Therefore, the flow of condensed water is as low as possible, and a statistical analysis reveals a value of approximately 4.6% of the HPS consumed in the turbogenerator. The high cost of the fuel consumed in the auxiliary boiler is responsible for this situation (the organic combustible is not enough to produce the steam). Consequently, the auxiliary boiler production can be given by (7) where HPS_{total} is the total production of HPS and HPS_{recb} is the HPS produced in the recovery boiler.

$$HPS_{auxb} = HPS_{total} - HPS_{recb}$$
 (7)

The HPS_{total} can be given by (8), where HPS_{papm} is the high-pressure steam consumption of the paper machine, and HPS_{trbgnr} is the HPS consumed in the turbogenerator.

$$HPS_{total} = HPS_{trbgnr} + HPS_{papm}$$
 (8)

As HPS_{trbgnr} equals the sum of MPS, LPS and CW produced in the turbogenerator (6), after some calculations HPS_{total} is given by (9), where LPS_{mass} and MPS_{mass} are, respectively, the lowand medium-pressure steam consumptions of the mass chain of the mill, b_{LPS}^{auxb} and b_{MPS}^{auxb} are the low- and medium-pressure specific consumption by the auxiliary boiler, and HPS_{papm} is the high-pressure steam consumption by the paper machine.

$$HPS_{total} = \frac{Num}{Den}, with$$

$$Num = [MPS_{mass} + LPS_{mass} - (b_{LPS}^{auxb} + b_{MPS}^{auxb}) \cdot HPS_{recb} + HPS_{papm}] \cdot \frac{1}{0.954}$$

$$Den = 1 - \frac{1}{0.954} \cdot (b_{LPS}^{auxb} + b_{MPS}^{auxb})$$

$$(9)$$

The electrical energy production of the turbogenerator, after the elimination of the condensed water, is given by (10), where LPS_{total} and MPS_{total} are described by (11) and (12).

$$EE_{trbgnr} = 70.017 \cdot MPS_{total} - (10)$$
$$102.566 \cdot LPS_{total}$$

$$LPS_{total} = LPS_{mass} + b_{LPS}^{auxb} \cdot HPS_{auxb}$$
 (11)

$$MPS_{total} = MPS_{mass} + b_{MPS}^{auxb} \cdot HPS_{auxb}$$
 (12)

The electrical energy bought from the public power system is computed by (13).

$$EE_{EDP} = EE_{total} - EE_{trbgnr}$$
 (13)

The total electrical energy consumed in the mill must be minimized by (14), where B_{EE} is the energy balance matrix.

$$EE_{total} = B_{EE} \cdot T \cdot u \tag{14}$$

3. MATHEMATICAL FORMULATION

There are some issues that should be addressed in the production scheduling, as stated in (Leiviskä, 1982) and in (Uronen, 1981):

- (1) the final production must be accomplished within the planning time horizon, since delays in delivery times lead to economic losses;
- (2) the storage capacities should be used in order to avoid over- and underflows and also to
- (3) avoid production-rate changes, as these are responsible for additional costs due to efficiency breakdowns in almost all departments;
- (4) the maintenance shutdowns should be carefully planned so as to benefit the entire mill;
- (5) the end of one schedule plan should be seen as the beginning of the next one, and therefore the final storage levels should be predetermined;
- (6) some attention should be paid to the energy consumption, since the pulp and paper industry is highly energy-demanding.

The mathematical formulation must take account of all the aspects mentioned above. From these, it is essential to distinguish between objectives and constraints.

From the above statements, it is seen that in this problem two criteria are needed, given by (15) and (16) where ch(k,i), as stated in (Monteiro, 1992), is the production-rate change function (department i and instant k) defined in (17).

$$Obj1 = \min \sum_{k=0}^{N-1} \{B_{EE} \cdot T \cdot u(k)\}$$
 (15)

$$Obj2 = \min \sum_{k=1}^{N-1} \sum_{i=1}^{n} ch(k, i)$$
 (16)

$$ch\left(k,i\right) = \begin{cases} 1 \Leftarrow u_{i}\left(k\right) \neq u_{i}\left(k-1\right) \\ 0 \Leftarrow u_{i}\left(k\right) = u_{i}\left(k-1\right) \end{cases}$$
 (17)

The formulation will be completed by a constraint set definition:

• the accomplishment of final production, during the planning time horizon, must corroborate equation (18), where x_{mpap} stands for the paper machine buffer level and K_{fpap} represents the finished paper needed;

$$x_{mpap}(N-1) - x_{mpap}(0) = K_{fpap}(18)$$

- the planned maintenance shutdowns and the production restrictions expressed by (2);
- the minimum and maximum safety limits of all storage buffers, as stated in equation (3);
- the buffers' final state, which should be predetermined, as in (19) where x_{final} represents the intended final state of the buffers;

$$x(N) = x_{final} \tag{19}$$

• the contracted electrical power, which is time variant, should not be exceeded, as in (20) where $P_c(k)$ is the contracted power limit.

$$EE_{EDP}(k) \le P_c(k)$$
 (20)

4. THE GENETIC ALGORITHM

The optimization of objectives (15) and (16) cannot be achieved by traditional methods since it is a mixed integer problem. However, since genetic algorithms are able to solve mathematically ill-defined problems, they are a tool of great potential. In this work a GA multicriteria approach is used, based on constraint-handling techniques.

Several methods exist for handling constraints by genetic algorithms in optimization problems. The technique used here (Michalewicz, 1994) is based on preserving the feasibility of solutions by using specialized operators that are closed on the feasible part of the search space. These operators (crossover and mutation) transform feasible solutions into other feasible solutions. The basic idea behind this method lies (i) in the elimination of the equalities present in the constraint set and, (ii) in the use of specific operators that guarantee that individuals are kept inside the feasible space.

GAs have been used particularly in single-objective problems; nevertheless, most of the practical applications exhibit more than one objective to be attended to. In this work, the Pareto ranking method is used in order to properly select the next generation. This technique, which makes use of the definition of Pareto optimality, was first introduced by (Goldberg, 1989) and later redefined as a slightly different scheme in (Fonseca and Fleming, 1993). As proposed by Fonseca, an individual's rank corresponds to the number of individuals in the current population by which it is dominated; therefore, the heavily dominated individuals are given a worse chance of reproduction. This process ends with the fitness assignment by interpolating from the best individual to the worst, usually according to an exponential function, but possibly also using other types. Here the function expressed in (21) was used, where P is the rank of the best individual, and 0 < c < 1 is a constant.

$$f_i = \frac{c-1}{c^P - 1} c^{P-i}; i \in \{1, \dots, P\}$$
 (21)

The crossover and mutation operators employed in this algorithm were chosen from those found in the literature, and which, by simulation, proved to be the set with the best convergence time and with the best diversification in the trade-off surface. The uniform crossover is based on (Syswerda, 1989) and (Spears and De Jong, 1991),

where, at instant k, two vectors with dimension m, x_k^a and x_k^b , exchange genes i with each other; that is, $x_k^{a(i)}$ and $x_k^{b(i)}$ for $i=1,2,\ldots,m$, with probability p. Fig. 2 represents this crossover.

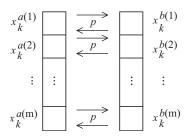

Fig. 2. Uniform crossover with probability p.

The mutation phase is formed by a set of four strategies: uniform, boundary, non-uniform (Michalewicz, 1994) and exchange mutations. Let $C = (c_1, \ldots, c_i, \ldots, c_l)$ be a chromosome of length l, and let $c_i \in [a_i, b_i]$ be the gene to which the mutation operator will be applied resulting in gene c'_i ; then in the uniform mutation c'_i is a random value, according to a uniform probability distribution, from $[a_i, b_i]$. In the boundary mutation c'_i is either a_i or b_i , with equal probability. In the non-uniform mutation, if g_{max} is the maximum number of generations, c'_i is given by (22), where $\alpha \in \{0, 1\}$ is a random binary digit, $\Delta(k, y) = y \cdot \beta \cdot \left(1 - \frac{k}{g_{\text{max}}}\right)^b$, β is a random number from the interval [0,1], and b is a parameter determining the dependence degree in the number of generations.

$$c_{i}' = \begin{cases} c_{i} + \Delta (k, b_{i} - c_{i}) \Leftarrow \alpha = 0 \\ c_{i} - \Delta (k, c_{i} - a_{i}) \Leftarrow \alpha = 1 \end{cases}$$
 (22)

Finally, in an exchange mutation, two consecutive genes c_i and c_{i+1} are exchanged for each other. This last type can be seen as a particular case of uniform mutation, where interval $[a_i, b_i]$ is simply c_{i+1} and $[a_{i+1}, b_{i+1}]$ is c_i .

The stochastic universal sampling is used in this work since it is considered the standard algorithm for sampling, which exhibits null distortion and minimum spread. For the reinsertion the elected mechanism was the generational reproduction (Syswerda, 1991) where the whole population is replaced in each generation.

The scheme of sharing was introduced in (Goldberg and Richardson, 1987), known as fitness sharing, and its main purpose is the distribution of the population in a set of niches in the search space. Use of this procedure eliminates the existence of similar individuals that would lead to redundancy, enemy of diversity. Equation (23) represents the shared fitness function, where nn_i is the niche number of individual i, as given in (24).

$$f_i^{share} = \frac{f_i}{nn_i} \tag{23}$$

$$nn_{i} = \sum_{j \in P} Sh\left(d\left(i, j\right)\right) \tag{24}$$

Function $d\left(i,j\right)$ enables the computation of the distance between individuals i and j, and represents the distance between the vectors formed by all the objective functions in the multicriteria problem. $Sh\left(d\right)$ is the sharing function as expressed by (25). σ_{share} represents the niche radius which, as stated in (Fonseca and Fleming, 1993), can be determined by (26), where n is the number of objectives, $D_{1i} = M_i - m_i + \sigma_{share}, \ D_{2i} = M_i - m_i, m$ and M are the minimum and the maximum of all objectives from the non-dominated set, $Q = \left(\frac{d}{\sigma_{share}}\right)^{\alpha_{share}}$ and α_{share} is a positive real.

$$Sh(d) = \begin{cases} 1 - Q \Leftarrow d \leq \sigma_{share} \\ 0 & \Leftarrow d > \sigma_{share} \end{cases}$$
 (25)

$$N \cdot \sigma_{share}^{n-1} - \frac{\prod_{i=1}^{n} D_{1i} - \prod_{i=1}^{n} D_{2i}}{\sigma_{share}} = 0 \quad (26)$$

Once the sharing scheme has been applied to the population, the crossover between individuals belonging to different niches may result in descendants in any niche. The mating restriction scheme (Deb and Goldberg, 1989) involves the parameter σ_{mate} which is quite similar to σ_{share} . The simplest mechanism using this approach is the mating radius which chooses as the second progenitor an individual from the mating pool at a distance less than σ_{mate} from the first progenitor. If none are in this situation, then a random individual is chosen.

5. APPLICATION TO THE MILL, AND SOME SIMULATION RESULTS

With the simplifications introduced in Section 2, three out of the ten mill departments can be determined subsequently; therefore, the scheduling problem is formed by seven departments. A discretization interval of four hours is used, in a planning horizon of forty-eight hours, which leads to eighty-four system variables. Each chromosome is then coded as real multiparameters, constructed from the concatenated codes. The population is composed of fifty individuals, and the initial ones are randomly generated feasible examples.

The initial and final buffer states are constrained to be 50% of their capacity and the final state for the finished paper is to be 90% of capacity. A shutdown in the paper mill is also imposed during the third discretization interval, and a reduction to 30% in the causticizing must occurs during the second discretization interval. Due to the limitations of the floating-point representation, a change in a production rate (17) is considered only if it is greater than 2% of the maximum.

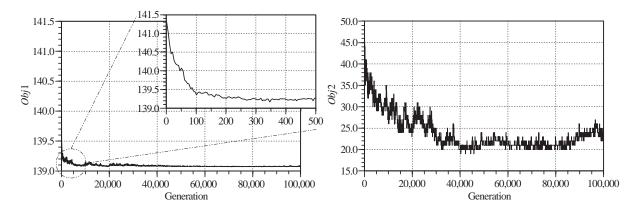

Fig. 3. Evolution of Obj1 and Obj2 across 100,000 generations.

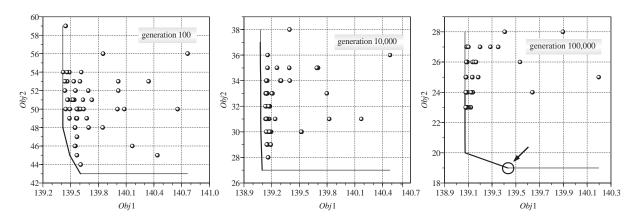

Fig. 4. The population and the cumulative trade-off surface in generations 100, 10,000 and 100,000.

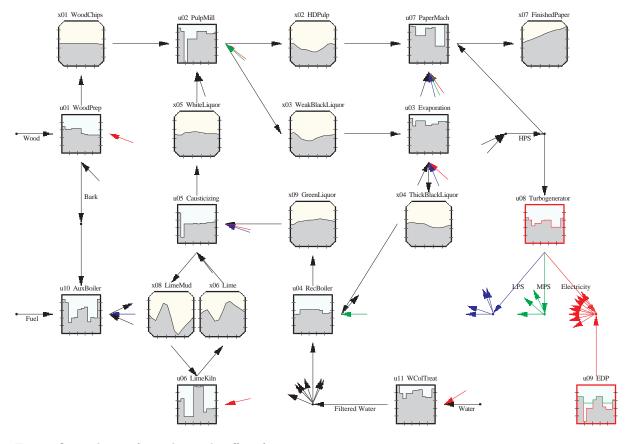

Fig. 5. One solution from the trade-off surface in generation 100,000.

Some simulation results are shown in Figs 3 to 5. The evolution of the best individual in the population across one hundred thousand generations is shown by Fig. 3. Fig. 4 depicts the population in three different generations as well as the cumulative trade-off surface. Finally, Fig. 5 represents the solution marked in Fig. 4, in generation one hundred thousand, being one of the possible solutions from the optimal Pareto set. These results show optimistic prospects for the potential of the GAs ability to solve this problem.

6. CONCLUSIONS

The aim of this work is to contribute to the development of an optimal scheduling system for the mass and energy production, with an application to a kraft pulp and paper mill. The dimensions of the problem, its multiobjective characteristic, and the presence of a high-order constraint set preclude the use of (only) traditional optimization techniques. The Pareto ranking method, and a technique that preserves the feasibility of the solutions, were used in a genetic optimization framework. In agreement with other studies (Santos, 1996), these methods and the genetic operators mentioned above (crossover, mutation, sharing and mating restriction) were those that revealed the best convergence time and the best diversification in the trade-off surface.

If a non-linear component were present in the constraint set, the system could be adapted using the proposal in (Michalewicz and Nazhiyath, 1995). In this way, the technique presented here exhibits a flexibility that is not achieved by traditional optimization methods. Further work will be needed in order to improve the convergence time, which is still the main drawback. Although the literature shows several applications with reasonable computational times in sequential architectures, it could always be possible to go over to parallel technologies, not necessarily using multiprocessors, but using existing resources such as personal computers and data networks.
